# 1 Background

Back in the mid-1980s, parallel programming techniques for HPC were still evolving, but by the early 1990s an effort to produce a standard message passing interface was under way, and the first MPI standard was completed in May 1994. The TotalView debugger, an already mature parallel debugger for the BBN Uniform System and Oakridge National Laboratory's Parallel Virtual Machine (PVM), was quickly adapted to support debugging MPI applications.

In early 1995, TotalView's Jim Cownie and Argonne National Laboratory's Bill Gropp and Rusty Lusk decided to join forces and develop debugging interfaces for use with MPICH, one of the first widely available MPI implementations. Two interfaces were developed: one for process discovery and one for message queue extraction. Coined the "MPIR" interfaces, the MPI debugging interfaces eventually became de facto standards implemented by various MPI providers such as Compaq, HP, IBM, LAM, MPI Software Technologies, Open MPI, Quadrics, SCALI, SGI, and other implementations of MPI.

Even though the MPIR debugging interfaces are still widely used today by a number of MPI implementations and tool vendors, MPIR has not yet been standardized. Bill Gropp writes, "...there never was a formal 'MPIR' spec for the process discovery - there was a hack that was created for the first prototype implementation with MPICH and the ch\_p4 device, but this was never intended to be a standard. Unfortunately, like so many prototypes, since there wasn't a standard, this part of the implementation was reverse-engineered into other implementations." In addition to being implemented by many MPI vendors, the MPIR Process Acquisition Interface used for process discovery has been extended by some vendors to better suit their needs.

This document describes the *state of the field* for the MPIR Process Acquisition Interface. It describes how the MPIR Process Acquisition Interface is currently used by several MPI implementations and tools.

# 2 MPIR Process Acquisition Interface Overview

The MPIR Process Acquisition Interface, also known as the MPI Automatic Process Acquisition (MPI APA) Interface, is used by tools such as debuggers and performance analyzers to locate MPI processes that are part of an MPI job. The tool can then automatically attach to the MPI processes in the job with no additional information required from the tool user. The MPI APA interface supports both launching an MPI job under the control of a tool and attaching a tool to an already running job.

The MPI APA interface is *not* an application programming interface (API). It is a rendezvous protocol used between the tool (such as a debugger or performance analyzer) and the MPI implementation. The MPI APA interface requires that the tool read symbol table information and trace the starter process, including starting and stopping the process, reading the memory and registers of the starter process, planting breakpoints, and handling events. MPI APA defines the starter process as the process that contains information about the location of the MPI processes. The starter process may or may not be an MPI process itself.

The MPI APA interface provides three fundamental pieces of information about each MPI process in an MPI job, as follows:

- 1. The location of the process in the form of a name that is resolvable to an IP address or node number.
- 2. The name of the executable the MPI process is running.
- 3. The process ID of the MPI process.

Collectively for each process, this information is known as the MPIR process descriptor. The MPI job control runtime system gathers the MPIR process descriptors into a single MPIR process descriptor table that is located in the memory of the starter process.

The MPI runtime system raises an event to the tool by setting an integer global variable and calling a breakpoint function in the starter process. The defined set of events is limited to MPI job spawn and abort. When the tool receives an MPI job spawn event, it reads the MPIR process descriptor out of the starter process and attaches to MPI processes.

Under the MPIR interface, the tool does not create the parallel job. The MPI job control runtime system creates the job and the tool attaches to the MPI processes *after* the processes have been created.

The MPIR interface also allows the MPI process to specify the path to the MPIR Message Queue Display (MQD) shared library, which allows the tool to display the state of the message queues in the MPI processes.

# 3 MPIR Process Acquisition Interface Definitions

This section contains definitions of terms used in the MPIR Process Acquisition Interface.

#### 3.1 MPI Process Definition

An MPI process is defined to be a process that is part of the MPI application as described in the MPI standard.

In this document, the rank of a process is assumed to be in **MPI\_COMM\_WORLD**. For example, "the MPI rank 0 process" means the MPI process that is rank 0 in **MPI\_COMM\_WORLD**.

#### 3.2 "Starter" Process Definition

The starter process is the process that is primarily responsible for launching the MPI job. The starter process may be a separate process that is not part of the MPI application, or the MPI rank 0 process may act as a starter process. By definition, the starter process contains functions, data structures, and symbol table information for the MPIR Process Acquisition Interface.

The MPI implementation determines which launch discipline is used, as described in the following subsections.

#### 3.2.1 The MPI Rank 0 Process as the Starter Process

The MPICH-1 p4 channel is implemented such that the MPI rank 0 process launches the remaining MPI processes of the MPI application. In MPICH-1 p4 channel implementation, the MPI rank 0 process is the starter process.

## 3.2.2 A Separate "mpiexec" as the Starter Process

Most MPI implementations use a separate "mpiexec" process that is responsible for launching the MPI processes. In these implementations, the "mpiexec" process is the starter process. Note that the name of the starter process executable varies by implementation and "mpirun" is a name commonly used by several implementations. Other names include "orterun", "srun", and "prun".

#### 3.3 MPIR Node Definitions

For the purposes of this document, the **host node** is defined to be the node running the tool process, and a **target node** is defined to be a node running the target application processes the tool is controlling. A target node might be the host node, that is, the target application processes might be running on the same node as the tool process.

# 4 MPIR Process Acquisition Interface Requirements

The MPIR Process Acquisition Interface requires the tool to contain several capabilities typically found in a debugger.

## 4.1 Symbol Table Requirements

The MPIR Process Acquisition Interface requires the starter process contain symbol table information for the functions, data structures, and types defined by the interface. The symbol table information must be contained within the starter process executable or a shared library used by the starter process. If the implementation places the symbol table information in a shared library, the shared library may either be loaded as a requirement of the starter process executable, or dynamically loaded at runtime by the MPIR starter process.

The symbol table requirements are as follows:

- The starter process compilation unit(s) containing the functions, data structures, and types defined by the interface must be built with symbolic debugging information (for example, on Linux, that typically means compiling with the "-g" option).
- The starter process implementation must ensure that the functions, data structures, types, and symbol table information are not discarded as a result of compiler or linker optimizations.
- The packaging, distribution, and installation procedures for the starter process implementation must ensure that the symbol table information is not stripped, separated or otherwise discarded.

# 4.2 Debugger-Level Process Control Requirements

The debugger-level process-control requirement is as follows:

• The MPIR Process Acquisition Interface requires that the tool be able to exercise debugger-level control over the starter process. The tool is required to be able control the execution, read and write the address space, plant breakpoints, and handle breakpoint events in the starter process.

# **5 MPIR Process Acquisition Interface Limitations**

The MPIR Process Acquisition Interface has the following limitation:

• The MPIR Process Acquisition Interface does not support the dynamic process creation or communication facilities of MPI 2, such as MPI\_Comm\_spawn, MPI\_Comm\_accept, or MPI\_Comm\_connect.

# 6 MPIR Process Acquisition Interface Models

The MPIR Process Acquisition Interface supports several process acquisition and synchronization models to accommodate various MPI implementations and tools deployment scenarios, as described in the following subsections.

#### 6.1 MPIR Job Launch and Attach Models

The MPIR Process Acquisition Interface supports both launching an MPI application under the control of the tool, and attaching the tool to an already running MPI application.

Under the MPIR **job launch model**, the tool is invoked on the starter process executable, which in turn starts the MPI application. Consider the following example command, where **tool** is the tool executable, **mpiexec** is the starter process executable and **mpiapp** is the MPI application executable:

```
$ tool tool-args mpiexec mpiexec-args mpiapp
s
```

Under the MPIR **job attach model**, the MPI job is already running when the tool is attached to the starter process, as shown in the following example commands:

Some amount of time elapses, and the tool is attached to the mpiexec process (perhaps because the job is hung), as follows:

```
\ tool tool-args -pid pid mpiexec \
```

# 6.2 MPI Process Synchronization Models

Under the job launch model the MPI implementation must ensure that the MPI processes do not return from **MPI\_Init**. This requirement guarantees that the tool can acquire the MPI processes early in their lifetime.

The MPIR Process Acquisition Interface provides an optional interface (see the description of MPIR debug gate variable named MPIR\_debug\_gate (§9.8)) that allows the tool to synchronize with the start up of the MPI processes. The goal of the MPIR debug gate is to prevent the MPI processes from "running away," before the tool has a chance to attach to them.

An MPI implementation is not required to use the MPIR\_debug\_gate variable for synchronization. In fact, implementations are encouraged to use a synchronization technique that does *not* involve the use of MPIR\_debug\_gate in the MPI processes. Other synchronization techniques include the following:

• The MPI processes form a barrier with the starter process. During startup, the MPI processes are created and allowed to run to barrier. The starter process joins the barrier, but only *after* it has set **MPIR debug state** (§9.6) to

- MPIR\_DEBUG\_SPAWNED (§9.6) and called the MPIR\_Breakpoint (§9.9) function to notify the tool of the spawn event.
- The starter process arranges for the MPI processes to be created in a stopped state, before they have executed any user-mode instructions. For example, on Posix-like systems, the MPI processes may be stopped on exit from execve. After the starter process has set MPIR\_debug\_state to MPIR\_DEBUG\_SPAWNED and called the MPIR\_Breakpoint function to notify the tool of the spawn event, the MPI processes are continued.

When an implementation uses a synchronization technique that does not use the MPIR debug gate, and does not require the tool to attach to and continue the MPI process, it should define the symbol MPIR\_partial\_attach\_ok (§9.13) in the starter process, and avoid defining MPIR debug gate in the MPI processes.

# 7 MPIR Process Acquisition Interface Extensions

MPIR has been extended by some vendors, as described in the following subsections.

#### 7.1 Tool Daemon Launch Extension

The MPIR Process Acquisition Interface does not specify how the tool launches its daemons, and does not support tool daemon launch.

However, the interface has been extended on IBM Blue Gene systems to support tool daemon launch, and that extension has also been implemented in Open MPI. The extension provides support only for tool daemon launch, not for communication between the tool and its daemons; the tool is responsible for establishing its own communication channels.

The tool daemon launch extension adds two character array variables to the MPIR interface that are named MPIR\_executable\_path (§9.16) and MPIR\_server\_arguments (§9.17).

They are used as follows:

- 1. Immediately after launching or attaching to the starter process, the tool writes the path name of its tool daemon's executable file to the MPIR\_executable\_path variable, and writes the tool daemon's command line arguments to the MPIR\_server\_arguments variable
- 2. The tool then sets **MPIR\_being\_debugged** (§9.3) to a non-zero value, and continues the starter process.
- 3. The starter process notices that the value of MPIR\_being\_debugged changed to a non-zero value, and launches the executable named by the MPIR\_executable\_path variable and passes the command line arguments contained in the MPIR\_server\_arguments variable.
- 4. It is then the responsibility of the tool and its daemon to establish communications.

See the description of the MPIR\_executable\_path and MPIR\_server\_arguments variables for more information.

# 7.2 Message Queue Display DLL Search Extension

The text from the follow Tex document should be integrated into this document:

https://svn.mpi-forum.org/svn/mpi-forum-docs/trunk/MPI-3.0/wg/tools/new-tools-chapter/chap-prof/symbol.tex

## 8 MPIR Process Acquisition Interface Use Case

Figure 1 shows a collaboration diagram of a typical MPI session under the control of a tool using the MPIR Process Acquisition Interface. Note that the interface can be used in several different ways, thus there are several different possible relationships. The collaboration diagram depicts one of the possible (and most common) relationships for an MPI implementation that uses a separate starter executable named "mpiexec" to launch a set of MPI tasks running an executable named "a.out".

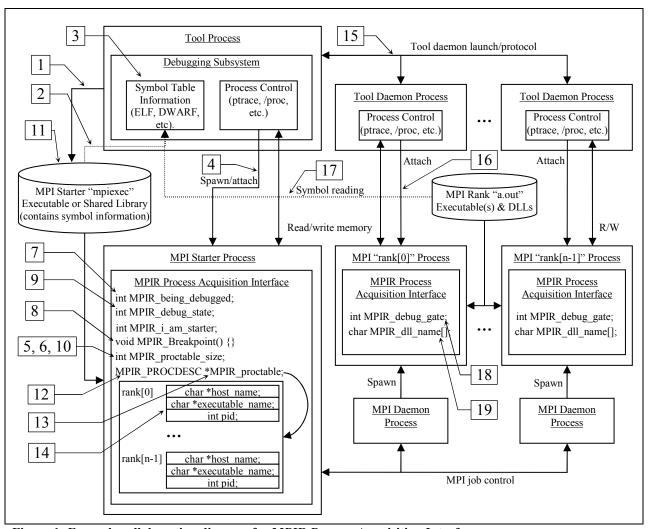

Figure 1: Example collaboration diagram for MPIR Process Acquisition Interface

#### Startup processing:

- 1. The tool is started on the "mpiexec" executable.
- 2. The debugging subsystem of the tool reads the symbol table information from the executable, and any shared libraries used by the executable.
- 3. The tool discovers the executable is a starter program by querying the symbol table for the MPIR Breakpoint symbol. If the symbol exists, then the tool should consider this a starter program.
- 4. The tool spawns or attaches to the starter process, and arranges for the starter process to remain stopped after the spawn or attach operation completes.
- 5. The tool reads the value of MPIR proctable size (§9.5) out of the starter process to determine the number of MPI processes already created by the starter process. If the tool spawned the starter process, then this value is expected to be 0. However, if the tool attached to the starter process, then this value could be greater than zero.
- 6. If **MPIR** proctable size is greater than zero, then the tool should attach to any additional MPI processes that might exist. If the symbol MPIR i am starter is not defined in the starter process, then the starter process is the MPI rank 0 process, thus the tool is already controlling the MPI rank 0 process.
- 7. The tool sets **MPIR** being debugged to 1 to inform the starter process that the debugger is present.
- 8. The tool plants a breakpoint at **MPIR** Breakpoint to receive MPIR events (defined below). The tool may then continue the starter process.

#### Event processing:

9. If the starter process hits the breakpoint at **MPIR** Breakpoint then by definition this raises an "MPIR event". The tool then reads the value of the MPIR debug state variable out of the starter process, and performs an action based on the variable's value, which typically results in the tool attaching to the MPI processes listed in the process descriptor table. See the description of MPIR debug state in section 9.6 for more information on MPIR events.

### Process descriptor table processing:

- 10. The tool reads the value of MPIR proctable size variable out of the starter process to determine the number of MPI processes already created by the starter process. If this value is not greater than zero, then the table is empty.
- 11. The tool determines the size and member layout of the MPIR PROCDESC (§9.2) process descriptor structure by reading the type information from symbol table of the starter process. The tool can find the process descriptor structure type information either using a lookup on the type name, or by looking up the MPIR proctable (§9.4) variable and dereferencing the variable's type. The latter approach is more reliable because the name MPIR PROCDESC is a typedef, which may not be available for by-name lookup.
- 12. The tool reads the value of the **MPIR** proctable pointer variable out of the starter process. The pointer is the base address of the process descriptor table.

- 13. The tool reads the process descriptor table out of the starter process, starting at the MPIR\_proctable pointer variable value. The length in bytes of the process descriptor table is the size of the MPIR\_PROCDESC process descriptor structure in bytes multiplied by the value of MPIR\_proctable\_size variable.
- 14. The tool iterates over the process descriptor table information to identify the node name or IP address, executable path name, and process ID of each of the MPI processes.
- 15. The tool launches its tool daemons, if necessary, on the set of nodes being used by the MPI processes.
- 16. The tool attaches to the MPI processes.
- 17. The tool reads the symbol table information of the MPI processes.

#### MPI process attach:

- 18. If the symbol MPIR\_partial\_attach\_ok is defined in the starter process, then this informs the tool that the initial startup barrier is implemented by the MPI system, and it is not necessary to set the MPIR\_debug\_gate variable in any of MPI processes. However, if the symbol MPIR\_partial\_attach\_ok is not defined in the starter process, the tool must attach and set the MPIR\_debug\_gate variable to 1 in each MPI processes to release them from the gate, even if the tool user has instructed the tool to not attach to all of the MPI processes.
- 19. The tool reads the value of the MPIR\_dll\_name (§9.14) character string variable out of the MPI processes. The string is the path name of a shared library that the tool can dynamically load into its own address space to gather MPI message queue information for the MPI process. The MPI Message Queue Display (MQD) DLL is described in a separate document. As an optimization, the tool can assume that the value of the MPIR\_dll\_name character string variable is identical for all MPI processes that are running the same executable. For example, in a single program multiple data (SPMD) style program, all MPI processes are running the same executable so the tool may assume that the value of MPIR\_dll\_name is the same in each process. In a multiple program multiple data (MPMD) style program consisting of two executables named "a.out" and "b.out", the tool may assume that all MPI processes executing "a.out" have the same MPIR\_dll\_name value, and all MPI processes executing "b.out" have the same MPIR\_dll\_name value, however the MPIR\_dll\_name value may differ between "a.out" and "b.out".

# 9 MPIR Process Acquisition Interface Specification

The MPIR Process Acquisition Interface is specified as a set of C-language definitions. The following sections enumerate those definitions. Each subsection covers one definition, specifies if the definition belongs in the starter process or the MPI processes, states whether or not the definition is required, and describes how the definition is used.

#### 9.1 VOLATILE

Macro definition:

```
#ifndef VOLATILE
#if defined(__STDC__) || defined(__cplusplus)
#define VOLATILE volatile
#else
#define VOLATILE
#endif
#endif
```

Definition is required.

Definition is used by the starter process and MPI processes.

The **VOLATILE** macro is defined to the **volatile** keyword for C++ and ANSI C. Declaring a variable **volatile** informs the compiler that the variable could be modified by an external entity and that its value can change at any time. **VOLATILE** is used with MPIR variables defined in the starter and MPI processes but are set by the tool.

## 9.2 MPIR\_PROCDESC

Type definition:

```
typedef struct {
  char *host_name;
  char *executable_name;
  int pid;
} MPIR_PROCDESC;
```

Definition is required.

Definition is contained within the symbol table of the starter process.

**MPIR\_PROCDESC** is a **typedef** name for an anonymous structure that holds process descriptor information for a single MPI process. The structure must contain three members with the same names and types as specified above. The tool must use the symbol table information to determine the overall size of the structure, and offset and size of each of the structure's members.

The **host\_name** member is a pointer to a null terminated character string in the address space of the starter process that specifies the target node location of the MPI process in the form of a host name or IP address string that must be translatable to an IP address. On Beowulf Distributed Process Space (BProc) systems, the string is an integer node number (e.g., "42").

The **executable\_name** member is a pointer to a null terminated character string in the address space of the starter process that specifies the name of the executable the MPI process is running.

The string should be the full path name to the executable, which may be relative to the host node or target node.

The **pid** member is the integer process identifier of the MPI process. Note that historically **pid** was defined as a C language int, which is an integer of an unknown size, which might be smaller than the size of a process identifier for the target system. Implementations should define **pid** as an integer size that is large enough to hold a process identifier for the target system. For example, implementations should use **pid** t as the type of **pid** provided that **pid** t is an integer type.

The MPI implementation should share the host and executable name character strings across multiple process descriptor entries whenever possible. For example, if all of the MPI processes are executing "/path/a.out", then the executable name field in each process descriptor should point to the same null terminated character string. Sharing the strings enhances the tool's scalability by allowing it to cache data from the starter process and avoid reading redundant character strings.

## 9.3 MPIR being debugged

Global variable definition:

VOLATILE int MPIR being debugged;

Definition is *not* required.

Definition is contained within the address space of the starter process.

Variable is written by the tool, and read by the starter process.

**MPIR** being debugged is an integer variable that is set or cleared by the tool to notify the starter process that a tool is present.

The tool sets the variable to 1 immediately after spawning or attaching to the starter process. The tool sets the variable to 0 immediately before detaching from the starter process.

The starter process may monitor the state of the variable and perform certain operations differently. For example, this variable might control whether or not the starter process forces the MPI processes to wait for the MPIR debug gate to be set.

# 9.4 MPIR proctable

Global variable definition:

MPIR PROCDESC \*MPIR proctable;

Definition is required.

Definition is contained within the address space of the starter process.

Variable is written by the starter process, and read by the tool.

MPIR\_proctable is a pointer variable set by the starter process that points to an array of MPIR\_PROCDESC structures containing MPIR\_proctable\_size elements. This array of structures is the process descriptor table.

The index position in the process descriptor table is the rank of the process in MPI\_COMM\_WORLD. For example, index 0 in the table specifies rank 0 in MPI\_COMM\_WORLD, index 1 in the table specifies rank 1 in MPI\_COMM\_WORLD, and so forth.

# 9.5 MPIR\_proctable\_size

Global variable definition:

```
int MPIR proctable size;
```

Definition is required.

Definition is contained within the address space of the starter process.

Variable is written by the starter process, and read by the tool.

**MPIR\_proctable\_size** is an integer variable set by the starter process that specifies the number of elements in the procedure descriptor table pointed to by the **MPIR proctable** variable.

## 9.6 MPIR\_debug\_state

Macro definitions:

```
#define MPIR_NULL 0
#define MPIR_DEBUG_SPAWNED 1
#define MPIR_DEBUG_ABORTING 2
```

#### Global variable definition:

```
int MPIR_debug_state;
```

Definition is required.

Definition is contained within the address space of the starter process.

Variable is written by the starter process, and read by the tool.

MPIR\_debug\_state is an integer variable set by the starter process that specifies the state of the MPI job at the point where the starter process calls the MPIR\_Breakpoint function. The starter process can raise an MPIR event in the tool by setting MPIR\_debug\_state and calling the MPIR\_Breakpoint function.

The tool must set a breakpoint at the **MPIR\_Breakpoint** function and read the value of the **MPIR debug state** variable to process an MPIR event. The following events are defined:

• If the value is **MPIR\_NULL** (0), then the tool should ignore the event and continue the starter process.

- If the value is MPIR DEBUG SPAWNED (1), then the starter process has spawned the MPI processes and filled in the process descriptor table. The tool can attach to any additional MPI processes that have appeared in the process descriptor table.
- If the value is MPIR DEBUG ABORTING (2), then the MPI job has aborted and the tool can notify the user of the abort condition. The tool can read the reason for aborting the job by reading the character string out of the starter process, which is pointed to by the MPIR debug abort string variable in the starter process.

The tool may continue or leave the starter process stopped after processing the event. The tool decides when to continue the starter process. For example, a debugger may allow the user to control the execution of the starter process in conjunction with controlling the execution of the MPI processes. However, a performance analyzer might automatically continue the starter process after processing the MPIR event. Note that some MPI implementations may require that the starter process be running while one or more of the MPI processes are running. Therefore, the tool may be required to implicitly continue the starter process when any of the MPI processes are continued.

# 9.7 MPIR\_debug\_abort\_string

Global variable definition:

```
char *MPIR_debug_abort_string;
```

Definition is *not* required.

Definition is contained within the address space of the starter process.

Variable is written by the starter process, and read by the tool.

**MPIR** debug abort string is a pointer to a null-terminated character string set by the starter process when MPI job has aborted. When an MPIR DEBUG ABORTING event is reported, the tool can read the reason for aborting the job by reading the character string out of the starter process. The abort reason string can then be reported it to the user, and is intended to be a human readable string.

## 9.8 MPIR debug gate

Global variable definition:

```
VOLATILE int MPIR debug gate;
```

Definition is *not* required.

Definition is contained within the address space of the MPI processes.

Variable is written by the tool, and read by the MPI processes.

MPIR debug gate is an integer variable that is set to 1 by the tool to notify the MPI rank processes that the debugger has attached. An MPI rank process may use this variable as a synchronization mechanism to prevent it from running away before the tool has time to attach to the process.

An MPI implementation is not required to use the **MPIR debug gate** variable for synchronization. However, the MPI job control runtime system must prevent the created MPI rank processes from running beyond the return from the application's call to MPI Init.

## 9.9 MPIR Breakpoint

Global subroutine definition:

```
void MPIR Breakpoint() {}
```

Definition is required.

Definition is contained within the address space of the starter process.

**MPIR** Breakpoint is the subroutine called by the starter process to notify the tool that an MPIR event has occurred. The starter process must set the MPIR debug state variable to an appropriate value before calling this subroutine. The tool must set a breakpoint at the **MPIR** Breakpoint function, and when a thread running the starter process hits the breakpoint, the tool must read the value of the MPIR debug state variable to process an MPIR event.

## 9.10 MPIR i am starter

Global variable definition:

```
int MPIR i am starter;
```

Definition is required when the MPIR starter process is *not* also an MPI process.

This symbol must *not* be defined if the process is an MPI process.

Definition is contained within the address space of the starter process.

Variable is neither read nor written.

**MPIR** i am starter is a symbol of any type (preferably int) that marks the process containing the symbol definition as a starter process that is *not* also an MPI process. This symbol serves as a flag to mark the process as a separate starter process or an MPI rank 0 process.

If MPI rank process 0 is the starter process, this symbol must *not* be defined.

## 9.11 MPIR acquired pre main

Global variable definition:

```
int MPIR_acquired_pre_main;
```

Definition is *not* required.

Definition is contained within the address space of the starter process.

Variable is neither read nor written.

MPIR acquired pre main is a symbol of any type (preferably int) that informs the tool that under the MPI job launch model the MPI processes are stalled or stopped before entering the main subprogram (main in the C language).

If the symbol is defined, the tool may assume that the MPI processes to which it is attaching are stopped upon creation (for example, on exit from the execve system call or inside a shared library's init section code) and have not yet entered the main subprogram.

The presence or absence of this symbol may cause the tool to behave differently. For example, if this symbol is present, a debugger may choose to the display the source code of the main subprogram after acquiring the MPI processes during an MPI job launch startup. If the symbol is absent, then a normal display showing the place at which the code was executing may be shown.

## 9.12MPIR force to main

Global variable definition:

```
int MPIR force to main;
```

Definition is *not* required.

Definition is contained within the address space of the starter process.

Variable is neither read nor written.

**MPIR** force to main is a symbol of any type (preferably int) that informs the tool that it should display the source code of the main subprogram after acquiring the MPI processes. The presence of the symbol **MPIR** force to main does *not* imply that the MPI processes have been stopped before dynamic linking has occurred.

## 9.13 MPIR\_partial\_attach\_ok

Global variable definition:

```
int MPIR partial attach ok;
```

Definition is *not* required.

Definition is contained within the address space of the starter process.

Variable is neither read nor written.

MPIR partial attach ok is a symbol of any type (preferably int) that informs the tool that the MPI implementation supports attaching to a subset of the MPI processes.

If the symbol MPIR partial attach ok is present, then this informs the tool that the initial startup synchronization is implemented in such a way that the tool need not attach nor continue MPI processes that the user is not interested in controlling. For example, the MPI implementation synchronization startup may be implemented as a barrier, rather than by having each of the MPI processes hang in a loop waiting for the MPIR debug gate variable to be set by the tool.

Thus, the tool need only release the starter process to release the whole MPI job, which can therefore be run without requiring the tool to acquire all of the MPI processes included in the MPI job. This is useful in tools that include the possibility of attaching to processes later in the tool session (for example, by selecting only processes in a specific communicator, or a specific process in MPI\_COMM\_WORLD). This method of operation is preferred because operating on a subset of processes is a valuable feature on high-scale systems.

The tool may choose to ignore the presence of the MPIR partial attach ok symbol and acquire all MPI processes. The presence of this symbol does not prevent the tool from using the MPIR synchronization technique to acquire all of the processes, if it so chooses, because setting the MPIR debug gate variable (if present) is harmless.

The type or value of this symbol is not tested by the tool. The presence or absence of this symbol is all that is tested.

## 9.14MPIR dll name

Global variable definition:

```
char MPIR dll name[];
```

Definition is *not* required.

Definition is contained within the address space of the MPI processes.

Variable is written by the MPI process and read by the tool.

The use of this variable is deprecated.

MPIR dll name is a null-terminated character string that contains the pathname of a dynamically loadable message queue debugging shared library. The shared library is intended to be dynamically loaded into the address space of the tool itself. An MPI implementation can use this variable to override any default message queue debugging library the tool uses.

Unfortunately, this interface has the limitation that allows for naming only one library, thus on systems where various tools could be using different ABIs (e.g., 32-bit vs. 64-bit), there is no single right library name value. To fix this problem, use the interface described in the "Message" Queue Display DLL Search Extension" section.

# 9.15MPIR ignore queues

Global variable definition:

```
int MPIR_ignore_queues;
```

Definition is *not* required.

Definition is contained within the address space of the starter process.

Variable is neither read nor written.

**MPIR** ignore queues is a symbol of any type (preferably int) that informs the tool that MPI message queues support should be suppressed. This is useful when the MPIR Process Acquisition Interface is being used in a non-MPI environment.

# 9.16 MPIR executable path

Global variable definition:

```
char MPIR executable path[256];
```

Definition is *not* required.

Definition is contained within the address space of the starter process.

Variable is written by the tool, and read by the starter process.

**MPIR\_executable\_path** is a null-terminated character string that is written by the tool into the address space of the starter process. The string is the path name of the tool daemon's executable file on the target node.

When the tool then sets **MPIR\_being\_debugged** to a non-zero value and continues the starter process, the starter process notices that the value of **MPIR\_being\_debugged** changed to a non-zero value, and launches the executable named by the **MPIR\_executable\_path** variable and passes the arguments contained in the **MPIR\_server\_arguments** variable.

## 9.17 MPIR\_server\_arguments

Global variable definition:

```
char MPIR server arguments[1024];
```

Definition is *not* required.

Definition is contained within the address space of the starter process.

Variable is written by the tool, and read by the starter process.

**MPIR\_server\_arguments** is a sequence of zero or more null-terminated character strings followed by a null character that is written by the tool into the address space of the starter process. Each null-terminated character string is passed as a single argument to the tool daemon. A null character terminates the list. It is not possible to pass the empty string ("") as an argument.

For example, the following C string contains four arguments:

```
"-callback\010.0.0.10\0-name\0has spaces and\ttabs\0\0"
```

The starter process should split the above string into an argy-style vector as follows:

```
argv[0] = "-callback"
argv[1] = "10.0.0.10"
argv[2] = "-name"
argv[3] = "has spaces and\ttabs"
argv[4] = 0
```

When the tool then sets **MPIR\_being\_debugged** to a non-zero value and continues the starter process, the starter process notices that the value of **MPIR\_being\_debugged** changed to a non-zero value, and launches the executable named by the **MPIR\_executable\_path** variable and passes the arguments contained in the **MPIR\_server\_arguments** variable.
